

## Description

Display comprising an integrated loudspeaker and method for recognizing tactile contacts with a display

5

The invention relates to a combination consisting of a display and a loudspeaker in accordance with Claim 1 and method for recognizing tactile contacts with the display in accordance with Claim 10.

- 10 A large number of electronic devices, such as mobile telephones or personal digital assistants for example, have both a display for the visual representation of information and also a loudspeaker for the audible reproduction of information. As a result of the continuing advances in the levels of miniaturization of such types of
- 15 electronic devices, thought has been given for some time with regard to integrating components of the man/machine interface.

The developments in this direction have in the meantime progressed to the point where displays, in particular a liquid crystal display

20 (LCD) into which a loudspeaker is integrated, are at least in the prototype stage. Displays having an integrated loudspeaker are suitable above all for use in mobile telephones or generally in communication devices which comprise an optical and acoustic component in the man/machine interface and at the same time exhibit

25 small dimensions.

The advantage of integrating display and loudspeaker consists not only in the space saving aspect but also in reduced costs. Instead of two components, only one single component is required, even if it

30 is more complex. This facilitates the production of electronic devices in which these components are used.

With regard to the majority of displays having an integrated loudspeaker, at least one part of a sound-emitting surface is used

as the display. Such loudspeakers are also referred to as display loudspeakers. Typically, with regard to such integrated systems the display cover consisting of a transparent plastic, which is intended to protect the actual display against impact and scratching, also  
5 forms the sound-emitting surface ("membrane") of the loudspeaker.

A loudspeaker is known from GB 2360901 A in which an electronic display is used as the membrane. This loudspeaker is intended first and foremost for use with portable electronic devices. In  
10 particular, mobile telephones are mentioned as a field of application. In spite of the savings in terms of components resulting from this combination of loudspeaker and display, certain components of the man/machine interface of an electronic device are still always required such as a keypad or a microphone in the case  
15 of a mobile telephone, for example.

The object of the present invention is to improve a display having an integrated loudspeaker to the effect that a further saving of components in the man/machine interface can be attained.

20 This object is achieved by a display comprising an integrated loudspeaker having the features in accordance with Claim 1 and by a method for recognizing tactile contacts with a display having the features in accordance with Claim 10. Preferred embodiments of the  
25 invention are set down in the dependent claims.

One important concept of the invention consists in the fact that the display combined with a loudspeaker can be implemented as a touch-screen or touch-sensitive display. As a result, the display can be  
30 used for data input. The touch-sensitive display can take over at least a part of the functionality of a keypad. As a result, savings can be made in keypad components which as a rule are expensive and

complex in respect of production engineering. According to a further concept of the invention, savings are additionally made at least in part in components which are required for a touch-sensitive display. This is achieved according to the invention in particular  
5 by the fact that at least one part of the loudspeaker, in particular the at least one part of the sound-emitting surface of the loudspeaker which forms the display, forms a recognition means for tactile contact made with the display. Components of the loudspeaker are thus used both for the loudspeaker functionality and also for  
10 the touch-sensitive display functionality. As a result of this multi-function capability, further components of the man/machine interface for an electronic device can be saved.

In concrete terms the invention relates to a display with an  
15 integrated loudspeaker, which is touch-sensitive. In addition, at least one recognition means for tactile contacts with the display is provided.

As already mentioned, at least one part of the sound-emitting  
20 surface of the display which forms the loudspeaker can form a recognition means for tactile contact made with the display. In other words, the sound-emitting surface used for the touch-sensitive display simultaneously forms a recognition means for tactile contacts. For example, the sound-emitting surface can be used for  
25 forwarding pulses which are triggered by tactile contact with the display. The touch-sensitive display can also be used as a transmission means in order to convey tactile contacts made with the display to a further recognition means such as a sensor for example. This further recognition means can then evaluate the transmitting  
30 "tactile contact".

By preference, a recognition means for tactile contacts with the display is formed by means of at least one actuator of the loudspeaker and/or by means of at least one sensor, in particular an  
35 acoustic or optical sensor. In the former case, at least one

actuator of the loudspeaker has a dual function, namely it acts not only as an actuator but also as a sensor. Components for the touch-sensitive display can be saved as a result. In the latter case, special sensors are used which form a recognition means for tactile contacts with the display.

Such types of actuators and sensors are preferably located in the vicinity of the edge or at the edge of the sound-emitting surface of the loudspeaker. In the case of acoustic sensors, this arrangement presents itself for a precise detection of a tactile contact. For example, small microphones can be used at the edge of the sound-emitting surface as acoustic sensors. These microphones can detect a tone emitted by the sound-emitting surface whose frequency lies in a range which is inaudible to human beings. If the display is now touched for example by means of a pen, then changes occur in the acoustic decoupling through the sound-emitting surface and thus in the emitted tone. These changes can be detected by the microphones.

In a preferred embodiment of the loudspeaker, at least one actuator and/or sensor is/are located beneath the at least one part of the sound-emitting surface of the loudspeaker which forms the display. This presents itself first and foremost in the situation when a piezo-electric element is used as the actuator or sensor, which for example detects mechanical influences on the display resulting from tactile contacts. At least one actuator or sensor can also be located as an alternative or as an addition on the at least one part of the sound-emitting surface of the loudspeaker which forms the display. For example, piezo-electric elements used as actuators or sensors can be located directly on the side of the sound-emitting surface facing away from the acoustically active side, in other words beneath the sound-emitting surface.

In a particularly preferred embodiment, the at least one actuator comprises at least one piezo-electric element and/or one electromagnetic converter. In order to drive the sound-emitting surface, both piezo-electric elements (piezo-loudspeaker) and also  
5 electromagnetic converters (dynamic loudspeaker) can be used. For the loudspeaker functionality, these elements convert an electrical variable into a mechanical variable. Conversely, advantage can also be taken of the fact that these elements are also capable of converting mechanical variables into electrical variables. This  
10 functionality can be utilized for the detection of tactile contacts with the display. If separate sensors are used for the detection of tactile contacts with the display, then piezo-electric elements are preferred. Such types of sensors can have very small dimensions and are therefore well-suited for integration into a loudspeaker.

15 Finally, with regard to the loudspeaker according to the invention, evaluation means can also be provided for evaluating the signal delivered by at least one actuator and/or at least one sensor. These evaluation means can for example be integrated in a chip which is  
20 connected to the at least one actuator and/or the at least one sensor in such a way that it receives signals from these.

The invention also relates to a method for recognizing tactile contacts with the display which is touch-sensitive and is integrated  
25 into a loudspeaker. In this case, at least one part of a sound-emitting surface forms the display. Tactile contacts with the display are recognized by a recognition means.

For example, a tactile contact with the display can be recognized  
30 through a changed decoupling of sound by way of the sound-emitting surface of the loudspeaker and/or through changes in the standing waves or reflections on the surface. By preference, the changed

output of sound and/or a standing wave and/or reflections is/are  
picked up by using at least one sensor, in particular an acoustic or  
optical sensor. In this case, the changed decoupling of sound and a  
standing wave are picked up by way of an acoustic sensor, whereas on  
5 principle reflections can be detected both acoustically and  
optically.

By preference the loudspeaker emits an audio signal which has a  
frequency outside the audible frequency range of sound waves. A  
10 tactile contact with the display can be recognized on the basis of  
changes in the audio signal output. By preference, the audio signal  
is emitted together with audio signals whose frequencies lie in the  
range which is audible to human beings, in other words it is  
superimposed on these. As a result of the fact that the audio signal  
15 has a frequency outside the audible frequency range, it is  
imperceptible to a human being and thus does not impair the acoustic  
quality of an electronic device in which the method according to the  
invention is being used.

20 A tactile contact with the display can also be recognized by means  
of a reaction to at least one actuator in the loudspeaker, for  
example through a mechanical movement of an electromagnetic  
converter in the loudspeaker or of a piezo-electric element for  
driving the loudspeaker when tactile contact is made with the  
25 display. Accordingly, the at least one actuator preferably converts  
the force acting as a result of the tactile contact with the  
displays into an electrical signal which can then be further  
processed for detection of the tactile contact.

30 In order to recognize the position of a tactile contact on the  
display, it is possible for example to evaluate the time difference  
between electrical signals from at least two actuators which detect  
the tactile contact. An impedance measurement and/or a differential

level measurement using the level of at least two signals from different sensors and/or actuators and/or an attenuation measurement of sound waves emitted by the sound surface in order to determine the position of a tactile contact on the display is also possible.

5 Finally, multiple-path propagations and/or reflections of wave propagations triggered by the tactile contact with the display can also be evaluated on the surface. The results of these measurements and/or calculations, which can be performed as alternatives or collectively, can be used for the widest variety of control  
10 purposes. With regard to the evaluation of multiple-path propagations and/or reflections of sound waves emitted by the sound surface, a trained neural network is preferably used for signal processing, which enables a reliable recognition of the position of the tactile contact.

15 Further advantages and possible applications of the invention will emerge from the description which follows of exemplary embodiments with reference to the drawings, in which;

20 Figure 1 shows a first exemplary embodiment of a loudspeaker having an integrated display, in which sensors are provided for recognizing tactile contacts with the display, in top view;

25 Figure 2 shows the loudspeaker illustrated in Figure 1 in cross-section,

Figure 3 shows a second exemplary embodiment of a loudspeaker having an integrated display, in which tactile contacts  
30 with the display are recognized through a reaction to actuators in the loudspeaker; and

Figure 4 shows a third exemplary embodiment of a loudspeaker having an integrated display, in which sensors located beneath  
35 the sound-emitting surface of the loudspeaker are

provided recognizing tactile contacts with the display.

Figure 1 shows a loudspeaker having an integrated display 10. The loudspeaker 10 comprises a sound surface 12 with the display.

5 Symbols 14 are represented in order to visualize the display. These symbols can for example identify a certain function which is triggered by touching the display at the position occupied by the respective symbol. Typical functions can for example be simple functions such as display illumination "On/Off" and ring tone  
10 "On/Off", a loud/quiet control using a +/- regulator, a so-called slider, a more complex menu control facility or even a virtual keypad.

By preference, an LCD is used for the display. The LCD  
15 simultaneously serves as an approximately flat sound-emitting surface for the loudspeaker. In order to drive the sound-emitting surface, or sound surface, 12, the loudspeaker 10 comprises an actuator 16 which is located beneath the sound surface. More precisely, the actuator 16 is located on the side of the sound  
20 surface 12 which is facing away from the sound-emitting side. The actuator 16 can be a piezo-electric element or an electromagnetic converter, for example a coil in a magnetic field as in the case of a dynamic loudspeaker.

25 Two sensors 18 are located at each edge side of the approximately square sound surface 12. Eight sensors 18 are provided in total. The sensors 18 are preferably small microphones. They detect a tone which is emitted by the sound surface 12. This tone has a frequency which is outside the audible frequency range for a human being. If  
30 the sound surface with the display 12 is touched at a particular position for example by means of a pen, then the decoupling of the tone through the sound surface changes. This is registered by the sensors 18.

By this means it is possible to detect a tactile contact with the display and to recognize on the basis of the special arrangement of the sensors where approximately the contact took place on the display. If for example the symbol 14 in the lower left corner of the sound surface 12 bearing the display is touched by a user using a pen, then the decoupling of the tone in this area of the sound surface 12 is particularly strongly influenced, with the result that the sensors 18 located in the vicinity of this area deliver a particularly intensive recognition signal which is processed accordingly by evaluation electronics connected downstream.

The loudspeaker with integrated display 10 illustrated in Figure 1 is shown in cross-section in Figure 2. The actuator 16 is located between the sound surface bearing the display 12 and a board 20 on which the loudspeaker 10 is mounted. On the board 20 are also mounted the sensors 18 and also a chip 22. The chip 22 is used for evaluating the recognition signals generated by the sensors 18 and also for driving the display in the sound surface 12. In other words, the chip 22 controls the input and output functionality of the display in the sound surface 12. To this end, the chip 22 is connected by way of electrical lines 24 on the board to the sensors 18 and to the display in the sound surface 12. By preference, it comprises an integrated signal processing circuit, for example a signal processor or a neural network for processing the signals delivered by the sensors 18 and an LCD drive unit for the representation of symbols 14 on the display in the sound surface 12.

Figure 3 shows a loudspeaker 10 with integrated display, in which actuators 17 are used which each comprise an integrated sensor. Actuators of this type can for example be conventional electromagnetic converters or piezo-electric elements for driving the sound surface of the loudspeaker. The electromagnetic converters

or piezo-electric elements are conversely also used here for the detection of a force acting on the display or sound surface and thus serve as sensors.

5 The actuators 17 are located with an approximately even distribution over the area which is covered by the sound surface 12 with display of the loudspeaker 10. By this means, tactile contacts over the entire area used for the display can be detected. The resolution for  
10 detecting the position of a tactile contact on the display is influenced by the number of actuators. For detection with a medium resolution, a smaller number of actuators is sufficient, six for example. This means that a costly conventional touchscreen whose complexity is unnecessary for a large number of application instances can be saved.

15 An evaluation and control circuit is used for evaluating signals which are generated by the integrated sensors of the actuators 17, in particular when a tactile contact is made with the display in the sound surface 12. In addition, control signals 26 are generated by  
20 the evaluation and control circuit 28, which are used for controlling the actuators 17 and thus for the output of sound by way of the sound surface 12. The evaluation and control circuit can be coupled by way of external signals 30 with further electronic components, for example in a mobile telephone or personal digital  
25 assistant, in which the loudspeaker 10 can be used.

Figure 4 shows a loudspeaker 10 with integrated display in which an actuator 16 is located approximately centrally on the sound surface 12 with display, more precisely beneath the sound surface 12 for  
30 driving the latter. In the edge zone beneath the sound surface 12, sensors 32 which are used for the detection of tactile contacts on the sound surface with display 12 are likewise located with an approximately even distribution. With regard to this embodiment, as in the case of the loudspeaker shown in Figures 1 and 2 separate  
35 actuators and sensors are used. A tactile contact on the display is

indicated by means of the illustrated pen 34 which touches the sound surface 12 with display and thereby generates a wave 36. The wave can be detected by the sensors 32 which can be implemented as piezo-electric elements.

5

The sensor signals 38 delivered by the sensors 32 are routed to an evaluation and display control circuit 40. The evaluation and display control circuit 40 evaluates the sensor signals 38 delivered by the sensors 32 and controls the display in the sound surface 12  
10 by way of display signals 42. The evaluation and display control circuit can be connected by way of external signals 44 to further electronic circuits, for example for signal processing and/or controlling the display and/or the loudspeaker.

15 Note: The basic idea (and probably the most immediate embodiment) of the reported invention is to detect tactile contacts on the display using only 1 or 2 actuators, without additional sensors (advantage: cost savings, disadvantage: low detection accuracy where the display has been touched). I would find it useful for this purpose to  
20 include an embodiment with an illustration in the application.
